SKYGUARD AI: AN AI-POWERED DIGITAL AIRSPACE SAFETY MONITORING AND PREDICTIVE COLLISION AVOIDANCE SYSTEM

A Software-First Digital-Twin Prototype for Weather-Aware Airspace Risk Analysis

Abstract
Airspace safety requires continuous awareness of aircraft position, altitude, speed, heading, traffic density, weather, restricted regions, and the availability of safe routes. SkyGuard AI is a software-first research prototype that models these conditions inside a controlled digital twin of simplified airspace. The system simulates aircraft telemetry, updates future trajectories, identifies possible conflicts, evaluates weather and airspace hazards, classifies risk, and recommends a safer simulated maneuver such as turning, climbing, descending, holding, continuing, or issuing an alert. The architecture separates aircraft simulation, visualization, environmental analysis, risk assessment, decision logic, and event logging so that each component can be examined independently. A seven-stage demonstration scenario shows two aircraft approaching a predicted trajectory conflict, an alternative route affected by a simulated storm, combined risk reasoning, and a recommended maneuver that resolves the simulated conflict. The prototype is intentionally positioned as decision support rather than a system that controls real aircraft. The current implementation uses simulated aircraft and weather information and therefore does not establish operational safety, certification, or statistical validation. In particular, the supplied project material does not contain a ground-truth conflict dataset, precision or recall measurements, false-alarm rates, latency benchmarks, or a validated machine-learning model. These limitations define the prototype as a proof of concept and motivate future work involving real data sources, richer trajectory models, uncertainty estimation, advanced machine learning, and quantitative evaluation.

Keywords: airspace safety; predictive collision avoidance; digital twin; aircraft simulation; weather-aware routing; risk analysis; AIdecision support; trajectory prediction; safe-flight zones; aviation monitoring.

I. INTRODUCTION
Modern air traffic management is fundamentally a problem of continuous situational awareness under uncertainty. Aircraft move through a shared three-dimensional environment while their positions, altitudes, velocities, headings, and intended trajectories change over time. At the same time, the environment itself can change because of weather, restricted airspace, traffic density, and operational constraints.
A monitoring system that considers only the current position of an aircraft can therefore miss an emerging conflict whose consequences become apparent only after the trajectories are projected into the future.

SkyGuard AI was conceived as an educational and demonstrative software prototype for exploring this predictive perspective. Instead of attempting to reproduce the full complexity of operational aviation systems, the project constructs a controlled digital twin in which aircraft, environmental hazards, and airspace constraints can be simulated and visualized. The central research idea is to combine multiple safety factors in a single decision-support workflow rather than presenting collision risk, weather, and airspace restrictions as isolated functions.

The project blueprint explicitly defines the system as decision support and not as a controller of real aircraft. This distinction is important. A prototype can demonstrate computational reasoning, interface design, trajectory prediction, and safety- oriented recommendations without making the much stronger claim that its logic is ready for operational aviation. The present work therefore concentrates on architecture, methodology, simulation behavior, and a clear pathway toward future empirical validation.

Within this scope, SkyGuard AI addresses a representative question: can a software system monitor simulated aircraft and environmental conditions, predict whether future trajectories may create a conflict, classify the associated risk, and recommend a safer maneuver before the predicted conflict occurs? The prototype considers aircraft position, altitude, speed, heading, proximity, relative motion, weather, traffic density, restricted regions, and projected trajectories as inputs to the decision process.

The remainder of this paper develops the concept in detail. It first describes the problem and objectives, then discusses the aviation context and related safety concepts. The system architecture, data model, trajectory reasoning, weather model, risk classification, safe-zone generation, and decision engine are subsequently presented. The paper then explains the interactive dashboard and demonstration scenario, discusses implementation and prototype

observations, defines a future evaluation framework, identifies limitations and safety considerations, and concludes with directions for extending the prototype into a more rigorous research platform.

II. PROBLEM STATEMENT AND RESEARCH MOTIVATION

A conventional monitoring display primarily answers the question of where aircraft are now. Predictive safety support must additionally answer where those aircraft are likely to be in the near future and whether their future states are compatible with safe separation. Two aircraft may currently be separated by a comfortable distance but have converging headings and speeds. Conversely, two aircraft can appear relatively close in a two-dimensional view while remaining acceptably separated because their altitude difference and motion provide additional separation.

The problem is further complicated by environmental constraints. An apparent alternative route may itself be unsafe because it passes through a severe weather region, a restricted zone, or an area of excessive traffic density. Therefore, a useful decision-support prototype should not treat collision risk and environmental risk as unrelated calculations. It should combine them so that the recommended maneuver reflects the interaction among traffic, trajectory, weather, and airspace availability.

The research motivation is consequently the development of an integrated, understandable, and modular prototype. The objective is not to replace certified aviation systems, but to provide a platform in which predictive reasoning can be demonstrated and later evaluated. Such a platform is valuable for academic experimentation because each module can be modified without rebuilding the entire system.

III. OBJECTIVES AND RESEARCH QUESTIONS

The primary objectives of SkyGuard AI are summarized below.

- Simulate and visualize multiple aircraft operating in a simplified three-dimensional airspace.
- Continuously track aircraft position, altitude, speed, and heading.
- Predict potential future trajectory conflicts rather than relying only on current proximity.
- Classify predicted situations into SAFE, WARNING, HIGH RISK, and CRITICAL categories.
- Model weather zones using rain intensity, wind speed, wind direction, visibility, and storm intensity.
- Represent safe, caution, danger, and restricted airspace in an interpretable visual form.
- Combine traffic, weather, collision-risk, and airspace information in a unified decision engine.
- Recommend simulated actions such as continue, turn, climb, descend, hold, or alert.
- Provide an interactive dashboard suitable for demonstration, analysis, and event-history review.
- Establish an architecture that can later accept real data sources and quantitative machine-learning evaluation. The central research questions are:

(1) how can future trajectory convergence be represented in a lightweight simulation;
(2) how can environmental hazards be incorporated into the same risk representation;
(3) how can a recommendation be generated while preserving interpretability; and
(4) how can the prototype be structured so that future empirical validation can be performed without redesigning the complete system?

IV. BACKGROUND AND RELATED WORK

Airspace safety is supported by several complementary layers rather than a single algorithm. Separation standards, surveillance, communication procedures, collision-avoidance technologies, and meteorological information each address different parts of the operational problem. This layered view motivates the architecture of SkyGuard AI, which similarly separates monitoring, environmental analysis, trajectory reasoning, and decision support.

The Federal Aviation Administration describes Reduced Vertical Separation Minimum operations in which aircraft at applicable flight levels may use 1,000 feet of vertical separation under specified requirements [2]. This illustrates why altitude cannot be ignored in a predictive airspace model. A two-dimensional representation may show an apparent crossing while the vertical dimension provides separation, or it may hide a future convergence that becomes important once altitude changes are considered.

The International Civil Aviation Organization describes Airborne Collision Avoidance System technology as a last resort safety net intended to reduce the risk of collision and improve alerting logic [3]. SkyGuard AI does not reproduce ACAS or claim equivalence with operational collision avoidance technology. Instead, the project explores a higher level educational concept: a software layer that reasons about future trajectories and combines the result with other simulated safety information before recommending a response.

Weather is another major component of aviation decision making. FAA material describes aviation weather information as important to safety and operational planning, while the NextGen Weather Processor combines multiple weather information sources to identify hazards and support prediction of route blockage and airspace-capacity constraints [4], [5]. The prototype adopts this broad systems principle but uses simulated weather zones rather than operational meteorological feeds.

From a digital-twin perspective, the prototype maintains a computational representation of a simplified environment whose state evolves over time. Aircraft state, environmental state, and airspace state can be modified independently, allowing repeatable scenarios. This repeatability is particularly useful for future research because the same initial condition can be replayed under different decision policies.

The contribution of the present prototype is therefore integration rather than invention of a new aviation standard. It brings aircraft simulation, future trajectory reasoning, weather-aware risk analysis, safe-zone

ISSN: 3107-6513

visualization, action recommendation, and event history into one interactive demonstration.

V. SYSTEM REQUIREMENTS

The system requirements are derived from the project blueprint and can be divided into functional and non functional requirements. Functional requirements include aircraft creation and state updates, telemetry display, trajectory prediction, conflict identification, weather-zone modeling, restricted-zone representation, risk classification, maneuver recommendation, scenario control, event logging, and visual feedback.

Non-functional requirements include modularity, interpretability, responsiveness, reproducibility, extensibility, and safe scope definition. Modularity allows the frontend, simulation engine, risk logic, and backend to evolve separately. Interpretability is important because a recommendation should be understandable to a human demonstrator rather than presented as an unexplained output. Reproducibility allows the same scenario to be replayed, while extensibility allows simulated inputs to be replaced by richer data sources in future research.

FUNCTION	DESCRIPTION
Monitoring	Track position, altitude, speed and heading
Prediction	Estimate future trajectory convergence
Risk assessment	Classify safety state
Weather analysis	Evaluate environmental hazards
Zone safety	Identify safe and unsafe regions
Decision support	Recommend a response
Event history	Preserve important events
Visualization	Support situational awareness

VI. PROPOSED SYSTEM ARCHITECTURE

SkyGuard AI is organized around five major functional areas: air traffic monitoring, predictive collision avoidance, weather analysis, safe-flight-zone generation, and an AI decision engine. These areas are supported by a visualization layer and an event-log component. The separation of concerns allows the prototype to demonstrate the complete safety workflow while keeping individual modules understandable.

The monitoring layer maintains the state of each simulated aircraft. A minimal aircraft record contains an identifier, position, altitude, speed, and heading. Additional fields can represent status, risk state, and scenario-specific metadata. The simulation engine updates these values as time advances, producing a continuously changing environment.

The predictive collision-avoidance layer examines relationships among aircraft. Distance, relative speed, heading, and altitude difference are treated as important inputs. The purpose is not to produce a certified separation calculation, but to determine whether the simulated future state enters a defined unsafe region. The result is converted into a qualitative risk class.

The weather analyzer models environmental zones using rain intensity, wind speed, wind direction, visibility, and storm intensity. These variables are used to classify a simulated weather region as SAFE, CAUTION, or DANGER. A route passing through a severe simulated storm can therefore receive a higher environmental penalty than an otherwise identical route through clear air.

The safe-flight-zone generator combines traffic, weather, collision risk, and restricted regions. Its output is a simplified representation of where flight is preferable, where caution is required, and where a route should be avoided. This layer is important because a maneuver is meaningful only relative to the airspace available to the aircraft.

The decision engine receives the combined state and considers candidate actions. The possible recommendations are continue, turn, climb, descend, hold, or alert. The recommendation is then returned to the dashboard, where the user can observe the effect on the simulated trajectory

VII. DATA MODEL AND STATE REPRESENTATION

The digital twin can be understood as a time-indexed state vector containing aircraft state, environmental state, and airspace state. For each aircraft, the position can be represented by horizontal coordinates and altitude, while speed and heading define its motion. The simulator advances this state at a selected playback rate.

A conceptual aircraft state can be expressed as $A_i(t) = \{p_i(t), h_i(t), v_i(t), theta_i(t)\}$, where p represents horizontal position, h represents altitude, v represents speed, and theta represents heading. The expression is a conceptual representation for the prototype and does not imply a complete aircraft dynamics model.

Environmental state contains weather regions and their associated attributes. A weather region can be represented by location, extent, visibility, wind characteristics, and storm intensity. Airspace state contains restricted regions, traffic-density information, and derived safe or unsafe zones.

The state model is deliberately modular. New attributes can be added without changing the fundamental processing sequence. For example, future versions could add uncertainty bounds, aircraft performance limits, route intent, or confidence scores. This extensibility is a prerequisite for later experimentation with more sophisticated prediction models.

VIII. TRAJECTORY PREDICTION AND CONFLICT DETECTION

Trajectory prediction is the core predictive component of SkyGuard AI. Rather than asking only whether two aircraft are currently close, the system examines how their relative states evolve. A simplified prediction can project each aircraft forward according to its current speed and heading and then evaluate the resulting separation over a future time window.

Let the predicted position of aircraft i at future time $t + Dt$ be represented conceptually by $p_i(t + Dt)$. For a pair of

ISSN: 3107-6513

aircraft i and j, a future conflict condition can be represented by a separation measure falling below a predefined simulated threshold while other conditions indicate convergence. The prototype uses this idea qualitatively; the supplied project material does not specify a validated aviation separation equation or operational threshold.

Relative speed and heading are important because distance alone does not reveal whether aircraft are approaching or diverging. Altitude difference adds a third dimension. A pair of aircraft with similar horizontal positions but substantial vertical separation may have a different risk state from a pair whose altitude is also converging.

The prediction module can operate as a repeated scan over relevant aircraft pairs. At each simulation update, it evaluates the current state, projects the near-future state, determines whether the projected state enters a simulated unsafe region, and passes the result to the risk classifier. Because the prototype is intended for demonstration, the computational model can remain lightweight while preserving the conceptual distinction between present position and future conflict.

The key benefit of this approach is early warning. If a conflict is identified while there is still sufficient simulated time to consider alternative actions, the decision engine can compare candidate maneuvers before the situation becomes critical.

IX. RISK CLASSIFICATION MODEL

The project defines four qualitative risk categories: SAFE, WARNING, HIGH RISK, and CRITICAL. These labels communicate the state of the simulation without claiming that the categories correspond directly to certified aviation alert levels.

Interpretation in prototype

No significant predicted conflict or environmental hazard Emerging convergence or moderate environmental concern Strong predicted conflict or combined hazards Immediate simulated safety concern

The classification can be viewed as the output of a rule-based or weighted decision layer. Relevant factors include predicted separation, relative motion, altitude difference, weather severity, traffic density, and restricted-zone interaction. A conceptual risk score R can be treated as a function of these variables: R = f(C, W, T, Z), where C represents collision related factors, W weather, T traffic conditions, and Z airspace constraints. The exact numerical weighting is not established by the supplied source and therefore should be treated as an implementation choice rather than a validated scientific result.

This distinction is essential for research reporting. A qualitative prototype can demonstrate the flow from sensor like inputs to risk categories, but quantitative claims require a defined dataset, ground truth, evaluation protocol, and statistical analysis. The present study intentionally does not manufacture such measurements.

X. WEATHER AND ENVIRONMENTAL HAZARD ANALYSIS

Weather is incorporated because a route that is safe from a collision perspective may still be undesirable because of environmental hazards. The prototype models rain intensity, wind speed, wind direction, visibility, and storm intensity. These variables are used to classify a simulated weather region as SAFE, CAUTION, or DANGER.

The environmental layer can be interpreted as a route feasibility filter. Candidate maneuvers are not evaluated only on whether they avoid another aircraft; they are also checked against the environmental state. A turn that avoids one aircraft but enters a simulated storm should therefore receive a worse decision score than a maneuver that avoids both hazards.

Future versions can make this model substantially richer. Historical weather observations or live weather APIs could be transformed into spatial hazard fields, while uncertainty could be represented by confidence regions rather than binary safe and unsafe boundaries. Such extensions would also make it possible to test how prediction quality changes as weather forecasts become less certain.

XI. SAFE-FLIGHT-ZONE GENERATION

The safe-flight-zone generator provides a spatial interpretation of the combined risk state. Instead of showing only individual alerts, it produces a simplified map in which regions can be categorized as safe, caution, danger, or restricted. This gives the decision engine a context in which candidate maneuvers can be compared.

A useful conceptual process is to begin with the simulated airspace, subtract restricted regions, mark weather hazards, add predicted conflict regions, and then identify remaining areas that satisfy the prototype's safety rules. The result is not intended to represent certified navigation data. It is an educational visualization of how multiple constraints can be combined.

The generated zones also support explainability. When a recommendation is shown, the user can inspect whether it was influenced by another aircraft, a weather region, a restricted area, or a combination of factors. This is preferable to treating the AI decision as a black-box action.

XII. AI DECISION ENGINE AND MANEUVER RECOMMENDATION

Alert and prioritize avoidance The decision engine represents the final reasoning stage of the prototype. It receives aircraft state, predicted conflicts, weather conditions, safe-zone information, and risk classifications. It then considers a set of candidate actions: continue, turn, climb, descend, hold, or alert.

A conceptual candidate score can be written as $S(a) = w_c C(a) + w_w W(a) + w_z Z(a) + w_t T(a)$, where a is a candidate maneuver and the terms represent collision, weather, airspace, and traffic penalties. The prototype blueprint does not define these weights, so the equation is presented as a research design abstraction rather than as an experimentally validated formula.

The most important design principle is that the recommendation should be constrained by the simulated environment. A maneuver should not be selected merely because it increases horizontal separation if it creates a

ISSN: 3107-6513

severe weather conflict or enters restricted airspace. This multi-factor reasoning is the main conceptual feature of SkyGuard AI.

The current project material describes advanced machine learning as future scope rather than as a validated component. Therefore, the present decision engine should be understood as AI-oriented decision logic and not as evidence that a trained machine-learning model has achieved a particular accuracy. A future ML version could learn risk scores or maneuver preferences from historical or synthetic trajectory datasets, but that extension would require independent training and evaluation.

XIII. SYSTEM WORKFLOW

The complete processing loop can be summarized as follows: • Aircraft State + Weather State + Airspace State
• Risk Analysis
• Future Trajectory Check
• AI Decision Engine
• Recommendation / Alert / State Update
• Dashboard Visualization and Event Logging

The workflow begins with the current digital-twin state. The simulation updates aircraft and environmental conditions, after which the risk layer evaluates current and predicted conditions. Future trajectory checks identify possible conflicts. The decision engine then compares candidate responses against the available simulated airspace. The selected recommendation is visualized and the resulting state is fed into the next simulation cycle.

This closed loop makes the prototype suitable for demonstrations because users can observe cause and effect. A conflict appears, the system identifies it, environmental information is considered, an action is recommended, and the updated state can be observed. Event history provides a record of these transitions.

XIV. USER INTERFACE AND INTERACTIVE DASHBOARD

The supplied prototype screenshot shows a dashboard oriented interface with a central airspace visualization, a control console, electronic flight strips, and an airspace-sector and fleet overview. Playback controls and simulation-speed controls support interactive exploration of the scenario. Aircraft telemetry and risk indicators provide detailed state information while the central visualization preserves the overall spatial context.

This layout is designed around situational awareness. A user can inspect an individual aircraft through its flight strip while simultaneously observing how the aircraft fits into the larger airspace. Risk indicators allow potentially important states to stand out without requiring the user to inspect every telemetry value manually. The interface also supports scenario-based demonstration. A presenter can select or replay a scenario, change the simulation speed, observe trajectory convergence, and follow the recommendation generated by the decision layer. This is particularly useful in academic settings because the prototype can demonstrate the complete system rather than only static screenshots.

The dashboard is also an important research instrument. In later versions, it can expose confidence values, prediction horizons, candidate maneuver scores, and event-log details. Such transparency would allow researchers to inspect not only what the system recommended but also why the recommendation was produced.

XV. IMPLEMENTATION ARCHITECTURE

The planned technology architecture uses React with Antigravity for the frontend and Python FastAPI for the backend. The frontend is responsible for visualization, controls, telemetry presentation, scenario selection, and user interaction. The backend provides the integration layer for simulation, risk logic, weather data, and event logging.

The architecture is intentionally software-first. The current prototype can operate with simulated aircraft and weather data and therefore does not require specialized aviation hardware. This makes the system accessible for educational development and rapid prototyping.

The project organization separates frontend and visualization, simulation engine, AI or risk logic, and backend or integration responsibilities. Testing, integration, presentation preparation, and final demonstration are shared activities. This separation mirrors the modular architecture and allows individual team members to work on different layers without creating unnecessary coupling.

The blueprint specifies a ten-day prototype strategy centered on live aircraft simulation, predictive collision detection, weather danger zones, safe-zone visualization, route recommendation, event history, and safety alerts. A physical layer using components such as an ESP32 or Arduino, LEDs, servos, and a buzzer is described as an optional later extension rather than a requirement for the core software prototype.

XVI. HERO DEMONSTRATION SCENARIO

The seven-stage demonstration is designed as a narrative sequence. In the first stage, two aircraft operate normally in the simulated airspace. Their current separation appears acceptable. In the second stage, their projected trajectories begin to converge. The system detects the convergence before the simulated conflict occurs.

In the third stage, the conflict is classified and surfaced through the dashboard. In the fourth stage, an alternative route is examined, but the system discovers a simulated storm zone on that route. This creates a multi-factor decision problem: avoiding the aircraft is necessary but entering the weather hazard is undesirable.

In the fifth stage, the system combines collision risk, weather conditions, altitude, heading, and available airspace. In the sixth stage, the decision engine recommends an appropriate maneuver such as a turn, climb, descent, or hold. In the final stage, the simulated trajectory is updated and the dashboard indicates that the conflict has been resolved.

This scenario demonstrates the central concept of the research: safety decisions should consider interacting conditions rather than treating collision risk and weather as unrelated screens. It also provides a reproducible structure

for future quantitative testing because the scenario can be executed repeatedly with different parameter values.

XVII. RESULTS AND PROTOTYPE OBSERVATIONS

The supplied prototype and project blueprint demonstrate an end-to-end conceptual workflow in which simulated aircraft are represented visually, safety states are surfaced through dashboard indicators, conflicts can be highlighted, weather and airspace conditions can be represented, and the decision layer can produce maneuver recommendations.

The prototype screenshot provides concrete evidence of interface-level integration. Multiple aircraft are represented in the fleet overview and electronic flight strips, while conflict and risk indicators are presented alongside the central airspace visualization. These observations support the claim that the prototype integrates the intended components at the demonstration level.

However, the available material does not provide a statistical test set or ground-truth conflict dataset. It also does not provide precision, recall, false-alarm rate, prediction horizon, computational latency, or a benchmark comparison against an operational collision-avoidance system. Consequently, the results should be interpreted as qualitative proof-of-concept observations rather than validated aviation performance.

The distinction between demonstrated functionality and validated performance is central to responsible reporting. The prototype demonstrates that the architecture can connect simulation, risk reasoning, environmental analysis, and visualization. It does not demonstrate that the system is safe for real aircraft or that its recommendations outperform established aviation technologies.

XVIII. EVALUATION FRAMEWORK FOR FUTURE EXPERIMENTS

A rigorous research evaluation can be introduced without changing the overall architecture. The first requirement is a controlled scenario dataset containing aircraft states, trajectories, environmental conditions, and a ground-truth label indicating whether a conflict exists within a defined prediction horizon.

Conflict-detection performance can then be measured using precision, recall, F1 score, false-positive rate, and false negative rate. Prediction horizon can measure how early a valid conflict is detected before the simulated loss-of separation event. Computational latency can measure the time between an updated state and the generated risk classification. Maneuver recommendation can be evaluated separately from conflict detection. A candidate maneuver can be labeled successful when it removes the predicted conflict without entering a higher-severity environmental or restricted region. Additional metrics can measure the number of alerts, unnecessary maneuver recommendations, and time available for response.

Weather-aware behavior can be evaluated through paired scenarios. The same traffic configuration can be executed once with clear air and once with a simulated hazard intersecting an alternative route. The expected behavior is that the decision engine changes its recommendation when environmental conditions make the original alternative undesirable. These experiments would transform the prototype from a demonstration into a research testbed. Importantly, evaluation should be conducted on scenarios that were not used to tune the decision rules or train a future machine-learning model. Separate development and evaluation sets would reduce the risk of reporting overly optimistic performance.

Purpose
Measure proportion of predicted conflicts that are valid
Measure proportion of conflicts detected Balance precision and recall.
Measure unnecessary alerts
Measure early-warning capability
Measure computational responsiveness
Measure whether recommendations resolve conflicts

XIX. ADVANTAGES

- Predictive orientation: focuses on future trajectory conflicts rather than only current proximity.
- Multi-factor reasoning: combines aircraft motion, weather, traffic, and restricted-airspace information.
- Visual situational awareness: combines map visualization, flight strips, telemetry, and alerts.
- Safe-zone representation: provides an intuitive distinction among safe, caution, danger, and restricted regions.
- Modular architecture: allows simulation, visualization, backend, and decision logic to be developed independently.
- Low-cost prototype path: demonstrates the concept using simulated data without specialized aviation hardware
. • Extensibility: supports future integration of real weather data, aircraft data, richer trajectory models, and machine learning.

XX. LIMITATIONS AND SAFETY CONSIDERATIONS

The first limitation is data realism. The prototype uses simplified simulated aircraft and weather data rather than operational surveillance and meteorological feeds. Real aircraft trajectories contain uncertainty, communication constraints, performance limits, navigation errors, and operational procedures that are not fully represented.

The second limitation is validation. The project blueprint does not establish certification, operational validation, or a safety assurance case. The system should therefore not be presented as an operational collision-avoidance system or as a replacement for certified aviation technology.

The third limitation concerns machine learning. Advanced machine-learning risk modeling is identified as future scope. Unless a trained model is independently implemented and evaluated, the present paper should not claim statistically validated machine-learning performance
. The fourth limitation is the simplified trajectory model. Aircraft performance is more complex than constant-speed or simplified heading-based movement. Turn rates, climb performance, wind effects, route constraints, and uncertainty can materially affect predicted trajectories.

The fifth limitation is environmental modeling. A simulated weather zone is a controlled abstraction. Real weather evolves continuously and may be represented by probabilistic forecasts rather than fixed regions. The prototype therefore demonstrates the architecture of weather-aware reasoning rather than operational weather avoidance.

These limitations are not merely weaknesses; they define the boundary of the research claim. By keeping the scope explicit, the prototype can be developed safely as an educational and experimental system while future work addresses the additional evidence required for stronger claims.

XXI. FUTURE SCOPE

Future development can replace simulated inputs with appropriate real-time or archived data sources in a controlled research environment. Real aircraft trajectory datasets would allow the conflict-prediction component to be tested against observed or synthetic ground truth, while weather APIs or historical weather datasets could provide more realistic environmental conditions.

An advanced machine-learning model could be trained on historical or synthetic trajectories. Candidate approaches could include classification for conflict probability, sequence models for trajectory prediction, or hybrid systems that combine learned estimates with explicit safety constraints. Such models should be evaluated with reproducible datasets and clearly reported metrics.

Uncertainty-aware prediction is another important extension. Instead of producing a single predicted position, the system could produce a probability distribution or confidence region around the future trajectory. Decision logic could then consider both expected risk and uncertainty.

The safe-zone generator could be expanded with detailed restricted-airspace geometry, traffic-density fields, route networks, and aircraft performance constraints. The event-log subsystem could support replay, comparison of alternative decisions, and post-event analysis.

The optional physical layer could connect the digital twin to LEDs, servo-controlled aircraft indicators, buzzers, or a physical control board. This would create a tangible demonstration of how digital safety states can be communicated through multiple channels while keeping the primary reasoning in software.

Finally, a future research platform could support controlled experiments comparing rule-based decision logic, optimization-based maneuver selection, and machine learning-assisted decision support. The existing modular architecture is suitable for such comparative studies because the decision layer can be replaced without redesigning the visualization and simulation components.

XXII. DISCUSSION

SkyGuard AI illustrates an important principle in intelligent safety systems: the usefulness of a recommendation depends on the context in which it is generated. A collision-only model may identify a geometrically attractive maneuver that is unacceptable once weather or restricted airspace is considered.

Conversely, a weather-only model cannot determine whether an aircraft is converging toward another aircraft. Integration is therefore not simply an interface convenience; it is the conceptual basis of the proposed decision-support workflow.

The digital-twin approach also offers advantages for experimentation. A controlled simulator makes it possible to reproduce scenarios, alter one variable at a time, and observe the resulting recommendation. This is more practical for early research than immediately depending on unpredictable live operational data.

At the same time, the prototype demonstrates why explainability and scope control are important in aviation oriented AI. A system that recommends a maneuver should make clear which simulated conditions influenced the recommendation and how confident the system is. The current prototype begins this process through visible risk categories, weather zones, telemetry, and dashboard events, but future work can make the reasoning more explicit.

The most appropriate interpretation of the project is therefore as a research-oriented prototype architecture. Its value lies in demonstrating a complete computational pipeline and creating a foundation for experiments, not in claiming that the prototype is ready for real-world deployment.

XXIII. CONCLUSION

SkyGuard AI presents a software-first digital-twin approach to airspace safety monitoring and predictive collision-avoidance decision support. The system integrates aircraft simulation, future trajectory reasoning, weather analysis, safe-flight-zone visualization, risk classification, and action recommendation within an interactive dashboard.

The central contribution of the prototype is the integration of multiple safety factors into one predictive workflow. Rather than waiting for current proximity to become dangerous, the system examines future trajectories and considers environmental constraints before producing a simulated recommendation.

The work is deliberately scoped as a controlled prototype rather than a real-world aircraft control system. Within that scope, it demonstrates how a modular software platform can anticipate simulated conflicts, combine traffic and weather information, and help users evaluate safer alternatives.

The next stage of research is quantitative validation. Realistic or synthetic benchmark datasets, ground-truth conflict labels, measurable prediction horizons, false-alarm analysis, latency measurements, and systematic comparison of decision policies are required before stronger performance claims can be made. Advanced machine learning, uncertainty-aware trajectory prediction, richer environmental models, and optional physical interfaces can then extend the platform into a more rigorous experimental research environment.

ACKNOWLEDGMENT

The authors acknowledge the project blueprint and prototype dashboard materials that formed the basis for the present research-oriented expansion. The work is presented as a software prototype study and does not claim operational certification or deployment in real aviation systems.

APPENDIX A. HIGH-LEVEL TECHNOLOGY ARCHITECTURE

XXIV. DETAILED RESEARCH DESIGN AND ENGINEERING ANALYSIS

The research design of SkyGuard AI follows a prototype oriented systems methodology. The objective is to construct a coherent computational pipeline in which simulated observations are transformed into a safety interpretation and then into a decision recommendation. This is different from a purely algorithmic study because the research question concerns the interaction among several modules. A trajectory predictor may be useful in isolation, but the prototype is specifically concerned with what happens when its output is combined with weather, traffic, and airspace constraints. The architecture therefore becomes part of the research contribution.

The study can be considered exploratory and demonstrative rather than confirmatory. No claim is made that the prototype has statistically established superiority over existing aviation systems. Instead, the study demonstrates feasibility at the software-prototype level and identifies the evidence required for later validation. This distinction also determines how results are reported. Observed dashboard behavior, successful completion of a demonstration sequence, and architectural integration can be reported as prototype observations. Numerical claims about detection quality require separate experiments and are intentionally excluded from the current evidence base.

A controlled digital twin is particularly appropriate for early experimentation because it allows the researcher to manipulate one variable while holding others constant. For example, two aircraft can be initialized with identical trajectories and then tested under different weather states. The resulting change in recommendation can be inspected without the uncontrolled variability of a live environment. Similarly, playback speed can be changed without changing the underlying scenario, allowing the interface and event sequence to be examined repeatedly.

The system is decomposed into state generation, prediction, environmental assessment, risk classification, decision support, visualization, and logging. State generation is responsible for producing the simulated world. Prediction transforms the current world state into an estimate of future aircraft relationships. Environmental assessment identifies weather and restricted-airspace concerns. Risk classification converts these observations into a small number of interpretable categories. Decision support evaluates possible actions. Visualization communicates the resulting state, while logging preserves events for replay and analysis. This decomposition reduces coupling. The simulation engine does not need to know how the dashboard is rendered, and the dashboard does not need to implement trajectory mathematics. The decision layer can receive structured state objects regardless of whether those states originate from a synthetic simulator or, in a future version, an external data source. Such separation is important for research because it permits controlled substitution of components. A future trajectory model can replace the initial predictor while the same visualization and logging infrastructure remain in place. The aircraft state representation is intentionally compact. Position, altitude, speed, and heading form the minimum set of variables identified in the project blueprint. Position provides spatial context, altitude provides vertical separation, speed determines how quickly the state can change, and heading determines the direction of horizontal motion. The combination permits a basic prediction of future relative geometry. Additional fields such as aircraft status, risk category, or selected scenario can be attached without changing the conceptual model.

A state update should be deterministic for a fixed scenario configuration. Determinism is useful because it allows a researcher to reproduce a conflict and compare different decision policies under identical initial conditions. If random variation is later introduced to model uncertainty, the random seed or scenario identifier should be recorded in the event history. Reproducibility is especially important when a future machine-learning component is introduced because model changes should be evaluated on consistent scenarios. The simplified aircraft model should not be interpreted as a flight-dynamics simulator. It abstracts away many physical and operational properties. For the purpose of the current research, the abstraction is useful because it isolates the decision-support concept. A future version can add aircraft specific performance envelopes, turn limitations, climb and descent constraints, or wind effects. Those additions should be introduced incrementally so that their influence on the recommendation can be measured rather than obscured by simultaneous architectural changes.

The prediction stage can be viewed as a short-horizon projection problem. At each update, the system estimates where each aircraft will be under the current motion

ISSN: 3107-6513

assumptions. Pairwise comparison then determines whether the projected states become sufficiently close to trigger a simulated conflict. The approach emphasizes the direction and evolution of motion. Two aircraft at equal current distance can produce very different outcomes if one pair is converging and another pair is diverging.

Prediction horizon is an important research variable even though the current prototype does not report a quantitative benchmark. A very short horizon may detect a conflict late, leaving little simulated time for alternative actions. A very long horizon can increase uncertainty and may produce warnings that later disappear. Future experiments should therefore test multiple horizons and examine the trade-off between early detection and false alerts. This would provide a measurable basis for selecting an appropriate prediction window for the simulator.

Relative motion is also central to the interpretation of trajectory convergence. If two aircraft have different speeds but similar headings, their separation can decrease gradually. If their headings cross, the minimum predicted separation may occur at a particular future time rather than immediately. A more advanced implementation could explicitly calculate the time of closest approach and use that value as an input to the risk classifier. Such an extension remains compatible with the current architecture because the classifier already consumes predicted conflict information.

Vertical movement introduces another dimension to the prediction problem. The blueprint identifies altitude difference as a relevant factor, and the demonstration includes maneuvers such as climb and descent. Future work can therefore model vertical trajectories separately from horizontal trajectories and combine them when evaluating separation. This would allow experiments in which a horizontal conflict is resolved through a vertical maneuver and vice versa, while still maintaining the prototype's simplified character.

The four-level risk classification is intentionally easy to understand. SAFE communicates that no significant simulated concern has been identified. WARNING indicates an emerging issue that merits attention. HIGH RISK indicates a stronger condition requiring active consideration of alternatives. CRITICAL indicates an urgent simulated condition for which an alert or avoidance recommendation is appropriate. The labels are interface abstractions and should not be confused with standardized operational alert levels.

A future implementation can convert the qualitative model into a transparent weighted score. For example, collision proximity, convergence rate, altitude difference, weather severity, traffic density, and restricted-zone interaction can each contribute a normalized component. The advantage of a transparent weighted model is that researchers can inspect the contribution of each factor. The disadvantage is that weights may be subjective. This creates an experimental opportunity: multiple weighting schemes can be compared using the evaluation framework described earlier.

A rule-based classifier may be preferable during the first stage of research because it provides deterministic behavior and is easy to debug. Once the scenario generator and ground-truth labels are established, a machine-learning model can be introduced as a controlled comparison. The rule-based system can act as a baseline, while a learned model can be evaluated against it using identical inputs and test cases. This approach avoids replacing a working baseline with a complex model before the measurement infrastructure exists.

The weather subsystem demonstrates how environmental information can alter a route decision. Rain intensity, wind speed, wind direction, visibility, and storm intensity are represented as simplified attributes of a weather zone. These variables need not be treated as independent. A future environmental score could combine them into a severity estimate, while retaining the individual attributes for explanation. The dashboard could then show both the overall classification and the underlying factors that caused it. Weather-aware routing is particularly important for the prototype's hero scenario because it creates a conflict between two apparently reasonable objectives. An alternative route may increase separation from another aircraft while simultaneously crossing a storm region. The decision engine must therefore consider the route as a whole rather than optimizing only one safety dimension. This is a simple but effective demonstration of multi-factor reasoning and provides a clear basis for future experiments.

A realistic weather extension would also introduce temporal evolution. A storm cell may move, intensify, weaken, or change its spatial extent. If the weather model becomes dynamic, the decision engine must evaluate both aircraft trajectories and environmental trajectories. This would turn route selection into a coupled prediction problem. The current modular architecture can accommodate such an extension because weather state is already treated as a separate input to the decision engine.

Safe-flight-zone generation converts multiple hazards into a spatial representation. The concept is useful because users often reason about routes spatially rather than through isolated numerical scores. A map can show a clear area, a caution area, a dangerous weather region, and a restricted region simultaneously. The decision engine can then select a maneuver whose projected path remains within acceptable areas. This also makes the prototype easier to demonstrate to audiences who are not familiar with aviation algorithms.

The zone generator should be treated as a derived visualization and decision-support layer rather than an authoritative navigation database. The geometry is simplified, and the source material does not establish operational airspace data. In a future research system, restricted regions could be represented using accurate geographic geometry, while weather and traffic risks could be rasterized or represented as spatial fields. The same conceptual pipeline could then operate at higher fidelity.

The decision engine can be implemented as a candidate generation and candidate-evaluation process. First, a set of possible actions is constructed. Second, each action is projected into the simulated environment. Third, the projected result is evaluated for collision, weather, restricted-airspace, and traffic penalties. Finally, the safest

ISSN: 3107-6513

acceptable candidate is selected, or an alert is produced when no candidate satisfies the simulated constraints. This process is more interpretable than directly producing a single unexplained action.

Candidate evaluation also provides a natural mechanism for explainability. The dashboard can display why an action was preferred: for example, a turn may be selected because it avoids a predicted conflict while keeping the aircraft outside a storm region. If another maneuver has a lower collision risk but a higher environmental penalty, the system can expose that trade-off. Such explanations would be useful for future human-in-the-loop experiments.

The action set of continue, turn, climb, descend, hold, and alert reflects the project blueprint. In a richer implementation, each action could have multiple parameter values, such as different turn magnitudes or altitude changes. The current study does not specify those parameters, so they should be treated as configurable simulation variables. This separation prevents a prototype-specific parameter choice from being mistaken for a real operational procedure.

The dashboard is not merely a presentation layer. It is part of the prototype's human interaction model. The central visualization provides spatial context, while flight strips and telemetry provide detailed state. Controls allow the user to manipulate playback and scenarios. Risk indicators focus attention on events that require interpretation. Together, these elements support a workflow in which the user observes the system, understands the simulated condition, and follows the recommended response.

Electronic flight strips provide a compact way to associate an aircraft identifier with its current telemetry and risk state. In future versions, each strip could include predicted conflict time, current recommendation, environmental exposure, and confidence. However, the interface should avoid displaying so much information that the main safety event becomes difficult to recognize. A useful design principle is progressive disclosure: present the most important state first and expose deeper diagnostic information when requested.

Playback control is particularly valuable for research demonstrations. A user can pause immediately before a predicted conflict, inspect the state, and then continue the simulation to observe the system response. The same capability can support debugging. When an unexpected recommendation occurs, the researcher can replay the preceding state transitions and identify whether the cause originated in simulation, prediction, weather assessment, or decision logic.

Event history is a core research capability because it turns a live simulation into a record that can be analyzed later. Events may include scenario start, aircraft-state updates, risk changes, conflict detection, weather warnings, recommendation generation, and conflict resolution. Each event should ideally contain a timestamp or simulation time, an aircraft identifier when relevant, an event category, and a concise description. The current blueprint identifies event logging as a system component without prescribing a detailed schema.

A structured event log also enables replay and comparison. Two decision policies can be run against the same scenario, and their event sequences can be compared to determine when they diverged. This capability becomes especially important when a machine-learning model is introduced. Researchers can inspect whether a model changes the timing of alerts, selects different maneuvers, or produces additional warnings compared with the baseline logic.

Testing should occur at multiple levels. Unit tests can verify individual functions such as distance calculations, state updates, risk classification, and weather scoring. Integration tests can verify that a predicted conflict reaches the decision engine and that the resulting recommendation appears on the dashboard. Scenario tests can verify complete narrative sequences such as the seven-stage demonstration. This layered strategy reduces the risk that an apparently correct interface hides an error in the underlying logic.

Boundary cases are particularly important. Aircraft that are far apart should not produce a high-risk state merely because their headings are similar. Aircraft that are close but vertically separated should be evaluated using the full simulated state. A route that crosses a danger weather zone should not be treated as equivalent to a clear route. Restricted zones should remain unavailable even when a maneuver would otherwise reduce collision risk. These cases provide useful regression tests for future changes.

The simulator should also test transitions between risk categories. A scenario may move from SAFE to WARNING as trajectories converge, then to HIGH RISK as predicted separation decreases, and finally back toward SAFE after a successful maneuver. Recording these transitions provides a more meaningful test than checking only the final state. It verifies that the system responds dynamically to changing conditions rather than producing a static classification.

A future experimental dataset can be generated systematically by varying initial position, altitude, speed, heading, weather placement, weather severity, and restricted-zone geometry. Each generated scenario can be assigned a ground-truth outcome using a trusted reference rule or manually verified simulation. The resulting dataset can support controlled experiments without relying immediately on operational aviation data.

Scenario generation should include both positive and negative examples. Positive examples contain genuine predicted conflicts, while negative examples remain safely separated. Additional hard negatives can include aircraft that pass close to each other but remain separated in altitude, or aircraft whose trajectories appear convergent at first but later diverge. Such cases are valuable because they test whether the predictor is actually reasoning about future motion rather than reacting to simple proximity.

Weather scenarios should also include benign and severe conditions. A clear-air baseline can be compared with a storm intersection case, and intermediate cases can test whether the risk classification changes gradually or abruptly. The objective is not to assert that a particular threshold is correct but to determine whether the system

ISSN: 3107-6513

behaves consistently with the rules defined by the research design.

Decision evaluation can use counterfactual comparison. For a given conflict, the system can evaluate several candidate maneuvers even if only one is ultimately recommended. Researchers can then inspect the safety factors associated with each candidate. This creates a richer dataset for future optimization or machine learning because it captures not only the chosen action but also the alternatives that were considered.

Reproducibility should be treated as a design requirement. Each demonstration scenario should have a stable identifier and a documented initial state. Software versions, configuration values, and random seeds should be recorded when applicable. If a future study reports that a decision policy resolves a particular class of scenarios, another researcher should be able to reconstruct the same class of scenarios and observe comparable behavior.

The prototype's modular structure supports reproducibility because each layer can expose its inputs and outputs. A saved scenario can feed the same aircraft state into two different prediction modules. The same predicted conflict can then be evaluated by alternative decision policies. This makes the platform more useful as a research instrument than a monolithic application in which simulation, prediction, and visualization are inseparable.

Although the current study is software-oriented, human factors remain relevant because the dashboard is intended for users who must interpret the system. Alerts should be noticeable without overwhelming the display. Risk categories should remain consistent. Recommendations should be phrased clearly, and the system should distinguish a predicted conflict from an already occurring simulated condition. These principles can later be evaluated through user studies, but the present prototype primarily establishes the interface foundation.

A human-in-the-loop extension could allow the user to accept, reject, or modify a recommendation. The system could then log the human action and compare it with the automated recommendation. Such a study would help evaluate whether the AI decision-support layer actually assists reasoning or merely adds another source of information. It would also provide a pathway for studying trust, explanation quality, and alert usefulness in a controlled environment.

A future networked version would introduce cybersecurity considerations. External data sources, APIs, user accounts, and event databases could become attack surfaces. The current simulated prototype avoids most of these concerns because its data is locally controlled. If external connectivity is added, input validation, authentication, authorization, secure communication, logging integrity, and failure handling should be addressed as engineering requirements.

Failure handling should be explicit. If a weather input becomes unavailable, the system should not silently treat the region as safe. If aircraft telemetry is stale, the dashboard should identify that condition. If the decision engine cannot identify an acceptable maneuver, an alert state should be generated rather than an arbitrary action. These behaviors are important for safety-oriented software because uncertainty or missing information can itself be a risk factor.

The prototype can therefore benefit from a distinction between safe, unsafe, and unknown states. The existing four-level risk classification focuses on safety severity, while a data-quality flag could indicate whether the underlying information is current and complete. This separation prevents a low-risk label from being interpreted as strong evidence when the input data is actually incomplete.

The architecture can be extended from a small number of aircraft to larger simulated fleets. The main computational challenge would be the number of aircraft relationships considered during pairwise conflict analysis. A future implementation can reduce unnecessary comparisons by using spatial indexing or sector-based filtering. Such optimization is not required for the current demonstration but becomes relevant if the simulator is used for larger experiments. S6 Conflict plus restricted zone The frontend can also separate high-frequency telemetry updates from lower-frequency risk summaries. Not every user interface element needs to refresh at the same rate as the underlying simulation. This distinction can improve responsiveness without changing the safety logic. A future benchmark should therefore measure both computational latency and interface responsiveness, because a fast backend does not automatically guarantee a usable dashboard.

Machine learning is best introduced after the baseline system and evaluation protocol are stable. A learned model can then be trained to estimate conflict probability, classify risk, predict future trajectories, or rank candidate maneuvers. The choice among these tasks should be guided by the research question. A model that predicts trajectories is not automatically a model that can safely recommend actions, and the paper should distinguish these functions clearly.

Synthetic data can provide an initial training resource because the simulator can generate many controlled scenarios. However, a model trained only on synthetic trajectories may learn simulator-specific patterns. A later study should therefore examine generalization across different simulation configurations and, where appropriate, compare against real or independently generated data. Model confidence and out-of distribution behavior should also be examined before making strong claims.

A hybrid approach may be particularly appropriate. Explicit constraints can enforce restricted-airspace and basic safety conditions, while machine learning can estimate uncertain quantities such as conflict probability or trajectory deviation. This allows the learned component to support decision making without being the sole authority. The modular design of SkyGuard AI is compatible with such a hybrid architecture. The research contribution can be summarized as a coherent prototype architecture and methodology for combining simulated aircraft trajectories with environmental and airspace constraints. The project does not claim a new aviation standard or a validated collision-avoidance algorithm. Instead, it demonstrates how several concepts can be integrated into an

interpretable digital twin and defines a path toward measurable evaluation.

This distinction also improves the academic value of the paper. A prototype study can be useful when it clearly identifies what has been implemented, what has been observed, and what remains to be validated. By explicitly separating those categories, the work avoids overstating the evidence while providing a concrete platform for subsequent experimentation.

XXV. PROPOSED EXPERIMENTAL SCENARIO MATRIX

The following matrix can be used as a future experimental plan. It is deliberately framed as a proposed evaluation structure rather than as completed experimental evidence.

Scenario family	Traffic condition
S1	Separated aircraft
S2	Converging aircraft
S3	Crossing trajectories
S4	Close horizontal spacing
S5	Conflict plus storm route
S6	Conflict plus restricted zone
S7	Multiple aircraft
S8	Repeated identical run

XXVI. RESEARCH DATA AND REPORTING PRINCIPLES

Every future experiment should record the scenario configuration, simulation time, aircraft states, environmental state, predicted conflict state, risk category, candidate actions, selected recommendation, and final outcome. The purpose of this structure is not to create an unnecessarily large dataset but to preserve enough information to reconstruct why a particular recommendation occurred.

Reporting should distinguish between implementation evidence and performance evidence. A screenshot can demonstrate that an interface element exists. A successful demonstration can show that a workflow can execute. Neither is sufficient to establish statistical accuracy. Performance claims should therefore be accompanied by a dataset description, ground-truth definition, evaluation metric, number of scenarios, and comparison baseline.

Negative findings should also be retained. If a candidate algorithm generates unnecessary alerts, that behavior is useful research information. Similarly, if a maneuver resolves a simulated collision conflict but enters a higher-severity weather zone, the case should be recorded as a failure of multi-factor decision logic rather than omitted from the evaluation. Transparent reporting will make later improvements more meaningful.

XXVII. EXTENDED DESIGN CHECKLIST

- Verify that every simulated aircraft has a complete and internally consistent state.
- Verify that trajectory prediction uses the latest simulation state.
- Verify that altitude is included whenever separation is evaluated.
- Verify that environmental hazards are passed to the decision layer.
- Verify that restricted regions remain unavailable to candidate maneuvers.
- Verify that risk categories change consistently as scenario conditions change.
- Verify that recommendations are logged with their triggering conditions.
- Verify that the dashboard distinguishes current state from predicted state.
- Verify that repeated runs of the same deterministic scenario produce the same event sequence.
- Verify that missing or stale inputs are not silently treated as safe. • Verify that future machine-learning experiments use separate development and evaluation data.
- Verify that all quantitative claims in later publications are supported by recorded evidence.

XXVIII. OVERALL RESEARCH SIGNIFICANCE

SkyGuard AI demonstrates how a relatively compact software prototype can serve as a bridge between classroom-level simulation and more rigorous intelligent-systems research.

The digital twin provides a controllable environment, the trajectory module introduces prediction, the environmental layer introduces contextual constraints, and the decision engine converts these observations into an interpretable recommendation. The dashboard then closes the loop by allowing a human observer to see the state and its evolution.

The most important next step is not simply adding more features. It is creating evidence. A research platform becomes substantially more valuable when each module can be measured, compared, and reproduced. The architecture presented in this paper is suitable for that transition because it separates the concerns required for controlled experimentation. A future study can therefore focus on one component at a time while preserving the same overall workflow.

In this sense, the current prototype should be understood as a foundation. It establishes a problem formulation, a system decomposition, a demonstration narrative, and a future evaluation methodology. The resulting platform can support research into trajectory prediction, weather-aware routing, explainable risk classification, hybrid AI decision support, and human-in-the-loop aviation interfaces without claiming that those research questions have already been solved.

XXIX. MODULE LEVEL IMPLEMENTATION SPECIFICATION

The frontend module is responsible for rendering the digital twin and exposing controls to the user. A useful implementation separates presentation state from simulation state so that temporary interface actions do not accidentally modify the underlying scenario. Scenario selection, playback speed, pause and resume, visualization filters, and aircraft selection can be treated as interface controls. The central visualization consumes structured state rather than implementing the underlying safety rules.

ISSN: 3107-6513

The simulation module is responsible for advancing the digital twin. At every simulation step, it reads the current aircraft state, applies the configured movement model, updates the environment when required, and publishes a new state. A stable simulation clock is preferable to relying exclusively on wall-clock time because it allows the same scenario to be accelerated, paused, or replayed without changing its logical sequence.

The trajectory module consumes aircraft states and produces predicted future relationships. Its interface can remain small: current state enters, predicted state and conflict information leave. This design allows the initial simplified predictor to be replaced by a more advanced model later. It also makes unit testing easier because a known input state can be paired with an expected qualitative result.

The weather module should treat each simulated weather region as structured data rather than as a visual overlay only. The decision layer must be able to query whether a candidate path intersects a region and, if so, retrieve the relevant severity attributes. This prevents a common architectural problem in which information is visible to the user but unavailable to the reasoning engine.

The restricted-airspace module performs a similar function for unavailable regions. A candidate maneuver should be evaluated against the same spatial representation that is displayed to the user. If the dashboard shows a region as restricted while the decision engine ignores it, the interface and reasoning layers become inconsistent. Maintaining a single source of structured zone information reduces this risk.

The risk module converts lower-level observations into a small set of categories. It should preserve the underlying factors so that the interface can explain the category. For example, a HIGH RISK state could expose whether its dominant contributor was predicted collision proximity, severe weather, restricted-airspace interaction, or a combination. This makes debugging and future validation more straightforward.

The decision module receives candidate actions and evaluates them against the simulated environment. Its output should include both the selected action and the reason or score components that produced the selection. Even if the initial implementation uses simple rules, recording those components prepares the system for later comparison with optimization or machine-learning approaches.

The event-log module should operate independently of the visual dashboard. This means important events are recorded even if a particular visualization component is temporarily disabled. A structured log also allows the same simulation run to be analyzed later without repeating the scenario. This is an important distinction between a demonstration interface and a research platform.

The backend integration layer provides a boundary between application logic and external data sources. The current prototype can use simulated inputs, but future versions may connect to weather services or stored trajectory datasets. Keeping this boundary explicit makes it possible to test the core reasoning system with both synthetic and externally sourced data.

XXX. PSEUDOCODE FOR THE CORE DECISION LOOP

• Initialize aircraft, weather regions, restricted zones, simulation clock, and event history.
• Read the current aircraft and environmental state.
• Advance the simulation by the selected time increment.
• Project relevant aircraft states over the configured prediction horizon
. • Evaluate predicted separation and identify candidate conflicts.
• Evaluate weather and restricted-airspace exposure for relevant routes. • Assign the qualitative risk category for each affected aircraft.
• Generate candidate actions including continue, turn, climb, descend, hold, and alert.
• Evaluate each candidate against collision, weather, traffic, and airspace constraints.
• Select the safest acceptable candidate or issue an alert when no acceptable candidate exists.
• Update the dashboard state and append the decision to the event history.
• Repeat until the scenario ends or the user pauses the simulation.

This loop is intentionally expressed as a conceptual sequence rather than a programming-language implementation. It captures the architecture described in the project blueprint and provides a reference for implementing individual modules without implying that a particular code structure is required.

XXXI. DATA FLOW AND INTERFACE CONTRACTS

A clean data flow is essential because the prototype combines several types of information. Aircraft data describes moving objects, weather data describes environmental regions, airspace data describes spatial constraints, and decision data describes the system's interpretation. These categories should remain distinguishable even when they are transmitted together in a single application state object.

An aircraft-state message can contain an identifier, horizontal position, altitude, speed, heading, risk category, and status. A weather-state message can contain a region identifier, location, severity, visibility, wind information, and storm intensity. An airspace-state message can contain region type, geometry, and availability. A decision message can contain aircraft identifier, recommended action, triggering risk, and explanatory factors.

Keeping these contracts stable makes the system easier to test. The frontend can use mock messages while the backend is being developed. The decision engine can be tested against recorded state messages without running the full interface. Conversely, the dashboard can be tested with synthetic decision messages without requiring the complete simulation engine.

Interface contracts also provide a path toward external data. If an archived trajectory dataset can be transformed

into the same aircraft-state representation used by the simulator, the prediction module does not need to know whether the state came from a simulator or a dataset. This is one of the strongest architectural benefits of separating data representation from data acquisition.

XXXII. SCENARIO PARAMETERIZATION

A research-grade simulator should expose scenario parameters rather than embedding every condition directly in code. Aircraft starting position, altitude, speed, heading, and identifier can be configurable. Weather regions can be moved, resized, and assigned different severities. Restricted zones can likewise be placed in different parts of the simulated airspace. This allows many experimental cases to be created from the same underlying scenario template.

Parameterization is especially useful for sensitivity analysis. A researcher can vary one parameter, such as initial heading, while keeping all other conditions fixed. The resulting change in predicted conflict or recommended maneuver can then be attributed more confidently to that parameter. Without parameterization, it becomes difficult to determine why a particular scenario produced a different outcome.

Scenario metadata should include the parameter values used to create the case. The event log can store the scenario identifier while a separate scenario definition stores the full configuration. This reduces duplication and allows the same scenario to be replayed without manually reconstructing every aircraft and weather region.

A scenario library can eventually organize cases into categories such as baseline, convergence, weather conflict, restricted-airspace conflict, multi-aircraft interaction, and failure-handling cases. Such a library would make demonstrations more consistent and would also provide a foundation for automated regression testing.

XXXIII. ERROR ANALYSIS STRATEGY

When the system produces an unexpected risk category, the first analytical question should be whether the input state is correct. A wrong aircraft position or stale weather state can propagate into every later module. The second question should be whether the trajectory prediction is correct for the simplified motion model. The third should be whether the risk classifier interpreted the predicted state according to its configured rules. Only after these layers are checked should the final recommendation be considered.

This layered error analysis follows the modular architecture. It prevents researchers from treating the final recommendation as a single black-box failure. A decision can be incorrect because the world state was wrong, because prediction was wrong, because risk classification was wrong, or because candidate evaluation was wrong. Recording intermediate states makes these distinctions observable.False alarms deserve special attention because a system that warns too frequently may reduce the usefulness of its own alerts. In the prototype, warning categories are intentionally qualitative. Future experiments should quantify how often the system flags scenarios that do not contain a ground-truth conflict. The objective is not simply to maximize sensitivity but to understand the trade-off between early detection and unnecessary warnings.

Missed conflicts are also important. A system that remains quiet during an actual simulated conflict may appear visually clean while failing its primary purpose. Future evaluation should therefore include both false positives and false negatives. The current prototype does not provide the data needed to calculate these quantities, which is why this paper treats them as future evaluation targets rather than present results.

XXXIV. COMPARISON BASELINES FOR FUTURE WORK

A future research study should compare the integrated decision engine against simpler baselines. One baseline could use current proximity alone, without trajectory prediction. Another could use trajectory prediction without weather or restricted-airspace information. A third could use a multi factor rule-based system. A machine-learning model could then be introduced as a fourth approach. Such comparisons would show whether each added layer contributes measurable value.

The current project does not contain the experiments needed to make these comparisons. However, the architecture naturally supports them because the decision layer can be configured to consume different subsets of information. The same scenario set can then be replayed across multiple policies. This makes the comparison more controlled than testing each method on a different dataset.

Baseline comparison is particularly important when reporting AI contributions. If a complex model does not improve performance over a simple rule-based predictor, the complexity may not be justified. Conversely, if a model improves prediction while preserving or reducing false alarms, the result would provide evidence for its usefulness. The prototype therefore provides a practical foundation for a future ablation study.

XXXV. ABSTRACTION BOUNDARIES

The system contains several deliberate abstraction boundaries. The first is between simulated aircraft and real aircraft. The second is between simulated weather and operational meteorological information. The third is between prototype risk categories and certified aviation alerting. The fourth is between AI-oriented decision logic and a statistically validated machine-learning model. Maintaining these boundaries prevents readers or users from interpreting a demonstration feature as an operational capability.

Abstraction is not inherently a weakness. In early research, a simplified environment can isolate the conceptual mechanism being studied. The important requirement is to describe the abstraction clearly and avoid conclusions that exceed it. Once the basic mechanism is understood, realism can be increased gradually and the effect of each increase can be measured.

The present paper therefore uses language such as simulated, conceptual, prototype, and future evaluation deliberately. These terms communicate the scope of the

ISSN: 3107-6513

evidence. They also make the research easier to extend because future studies can identify exactly which abstraction was replaced or refined.

XXXVI. EXTENSION TOWARD A RESEARCH PLATFORM

The transition from prototype to research platform can be organized into stages. Stage one is stabilization of the existing simulator and dashboard. Stage two is creation of a reproducible scenario library and structured event logs. Stage three is quantitative evaluation of the current rule-based logic. Stage four is introduction of richer trajectory and weather models. Stage five is controlled comparison with machine learning or optimization-based approaches.

Each stage should preserve the previous stage as a baseline. This allows researchers to determine whether a new component genuinely improves the system or merely changes its behavior. For example, a richer weather model should be evaluated against the original simplified weather model on the same scenario family. Similarly, a machine-learning predictor should be compared against the existing rule-based predictor before it is integrated into the final decision engine.

The platform can ultimately support multiple research questions rather than one fixed experiment. Researchers could investigate prediction horizon, explainability, human interaction, weather-aware routing, uncertainty modeling, or computational efficiency. The same dashboard and event-log infrastructure could support these studies, reducing development effort and improving comparability.

XXXVII. FINAL TECHNICAL SUMMARY

SkyGuard AI combines a simulated airspace state with predictive trajectory analysis, environmental hazard evaluation, risk classification, and maneuver recommendation. The system is intentionally modular: the frontend visualizes state, the simulator generates evolving conditions, the prediction layer estimates future relationships, the environmental layer evaluates weather and restricted regions, the risk layer classifies the situation, and the decision engine evaluates candidate responses.

The supplied project material supports the conclusion that this integrated workflow is suitable for a software demonstration. It also clearly identifies the boundaries of the present work: simulated inputs, simplified trajectories, optional future machine learning, and the absence of quantitative validation. The expanded research design in this paper converts those limitations into a concrete roadmap for future experiments.

The principal research value of the project is therefore its architecture and experimental potential. It provides a controlled environment for studying how multiple safety factors can be brought together before a decision is made. With a reproducible scenario library, structured event logging, ground-truth labels, and measurable evaluation metrics, the prototype can evolve into a platform for systematic research in intelligent airspace decision support.

XXXVIII. PRACTICAL DEVELOPMENT AND DEPLOYMENT CONSIDERATIONS

The software-first design makes SkyGuard AI suitable for incremental development. The initial deployment can remain entirely local, with the frontend communicating with a local backend and the backend generating all simulation data. This arrangement reduces external dependencies and makes demonstrations more predictable. It also allows the development team to focus on system behavior before introducing authentication, external APIs, or cloud infrastructure.

When the prototype is moved to a hosted environment, configuration management becomes important. Simulation parameters, API endpoints, and logging destinations should be separated from application code. A development environment can use synthetic data, while a research environment can use controlled datasets. This separation helps prevent accidental mixing of experimental and demonstration configurations.

Performance optimization should be guided by measurement rather than assumption. For a small simulated fleet, a straightforward pairwise conflict scan may be sufficient. As the number of aircraft grows, spatial indexing, sector filtering, or other techniques can reduce unnecessary comparisons. The research platform should record processing time so that an optimization can be evaluated quantitatively rather than judged only by subjective responsiveness.

Reliability should also be considered at the application level. The system should tolerate a paused simulation, invalid scenario configuration, missing weather information, and unexpected state transitions without crashing. A visible system-status indicator can distinguish normal operation from degraded operation. This is particularly useful in demonstrations because it prevents an interface problem from being mistaken for a decision-logic result.

XXXIX. EXPLAINABILITY AND TRUST

Explainability is particularly important when a system produces recommendations in a safety-oriented context. A user should be able to determine which conditions contributed to a recommendation. In SkyGuard AI, the relevant factors are already represented explicitly: trajectory convergence, altitude difference, weather severity, traffic density, and restricted airspace interaction. Exposing these factors in the interface would make the system easier to inspect.

An explanation can be structured around the decision chain. The system can state that a conflict was predicted, identify the environmental constraints affecting alternative routes, and show why the selected action had the lowest simulated risk. This does not require exposing internal implementation details. It requires presenting the decision-relevant evidence in a human-readable form.

Trust should not be equated with automation. A useful decision-support system may deliberately keep a human in the loop, especially while the prototype is being evaluated. A future interface could allow the user to inspect candidate maneuvers and acknowledge or reject the recommendation.

ISSN: 3107-6513

Every human override could then be logged for later analysis.

Such interaction would create a new research dimension. Researchers could study whether explanations change the user's understanding of the system, whether additional information improves or slows decisions, and whether users recognize the difference between a simulated prototype and an operational aviation system. These questions are beyond the current prototype results but follow naturally from its dashboard design.

XL. VALIDATION ROADMAP

The first validation milestone should be functional correctness. Every module should pass deterministic tests using known input states. The second milestone should be scenario correctness, in which complete demonstrations produce the expected qualitative sequence. The third milestone should be quantitative evaluation using a generated dataset with ground-truth labels. The fourth milestone should be comparative evaluation against simpler baselines

A fifth milestone can examine robustness. Scenario parameters can be perturbed slightly to determine whether the system behaves consistently. For example, small changes in speed or heading should not cause unexplained jumps in risk category unless they cross a defined decision boundary. Robustness testing is particularly useful before machine learning is introduced because it reveals weaknesses in the underlying problem formulation.

A sixth milestone can evaluate uncertainty. Prediction confidence can be introduced and compared with observed scenario outcomes. If the system is uncertain, it should ideally expose that uncertainty rather than presenting a low-risk category with unjustified confidence. This is an important direction for any future intelligent safety system.

final milestone can investigate human interaction. Users can be presented with simulated scenarios and asked to interpret the system's risk state and recommendation. Measures can include decision time, agreement with the simulated safety outcome, and frequency of unnecessary overrides. Such a study would require a carefully designed protocol and should be treated as a separate human-factors research activity.

XLI. ETHICAL AND RESPONSIBLE RESEARCH POSITION

Because the prototype concerns aviation safety, responsible communication is essential. The system should always be described as a simulated decision-support prototype unless and until independent validation establishes a stronger level of capability. The current evidence does not support claims of certification, operational deployment, or replacement of established aviation safety systems.

Research materials should clearly distinguish simulated results from real-world observations. A successful simulated conflict resolution sequence demonstrates behavior inside the model. It does not prove that the same maneuver would be safe for a real aircraft under operational conditions. Maintaining this distinction protects both the technical credibility of the research and the interpretation of its results.

Future use of real trajectory or weather datasets would also require appropriate consideration of data licensing, privacy where applicable, and research governance. The current prototype avoids these issues by relying on simulated information. If external datasets are introduced, their provenance and permitted use should be documented as part of the experimental methodology.

Responsible research also means reporting limitations openly. The absence of quantitative metrics in the current material is not something that should be hidden by presenting invented numbers. Instead, it should be identified as a clear next step. This paper follows that principle by describing a future evaluation framework without representing proposed metrics as measured results.

XLII. RESEARCH REPRODUCIBILITY PACKAGE

A reproducible future release should contain the source code, a versioned scenario library, configuration files, a description of the simulation assumptions, and instructions for running the demonstration. Each scenario should have a unique identifier and a short description. The event log should use a consistent schema so that results can be analyzed programmatically.

A research paper accompanying such a release should specify which software version generated each result. If a machine learning model is added, the release should also document the training data, preprocessing, model configuration, training procedure, and evaluation split. These details are not required for the current simulation-only prototype, but planning for them early prevents later experiments from becoming difficult to reproduce.

Reproducibility also benefits the user-facing demonstration. If a reviewer or evaluator can launch the same scenario and observe the same sequence, the paper's architectural claims become easier to verify. This is especially valuable for student research projects because a clear reproducibility package can demonstrate engineering maturity even when the experimental dataset is still being developed.

XLIII. CLOSING DISCUSSION

The expanded design presented in this paper shows that SkyGuard AI can be interpreted not merely as a dashboard application but as a modular experimental environment. The dashboard is the visible component, while the deeper research structure consists of state representation, prediction, environmental reasoning, risk classification, candidate evaluation, and logging. This distinction is important because it defines how the project can grow beyond its initial demonstration.

The current prototype has a practical advantage: its core workflow can be demonstrated without specialized hardware or operational aviation data. That lowers the barrier to experimentation and makes it possible to investigate concepts such as predictive conflict detection and weather-aware decision support in a controlled environment. The same software-first approach also

reduces the risk of confusing a physical demonstration with a validated aviation system.

The strongest future contribution would come from combining the existing architecture with systematic evaluation. Once scenarios are labeled, metrics are defined, and baselines are established, the project can move from a descriptive prototype study toward an empirical research study. The resulting evidence could then support more specific conclusions about prediction quality, decision quality, robustness, and computational efficiency.

In summary, the research direction is coherent: build the simulator, stabilize the architecture, record reproducible events, create a benchmark scenario library, evaluate the baseline, and only then introduce more complex models. This staged progression preserves the interpretability of the prototype while creating a defensible path toward advanced AI research.

XLIV. IMPLEMENTATION MILESTONES FOR FUTURE DEVELOPMENT

The first milestone is prototype stabilization. At this stage, the aircraft simulator, dashboard, risk indicators, weather zones, and event history should operate consistently under the supplied demonstration scenario. The main objective is repeatability rather than feature expansion. Every visible state should correspond to an underlying structured state, and important transitions should be recorded.

The second milestone is scenario-library development. The team can create a set of deterministic cases covering normal operation, predicted convergence, altitude-separated traffic, weather hazards, restricted zones, and combinations of these conditions. Each scenario should have a documented initial state and expected qualitative behavior. This library can serve both as a demonstration collection and as a regression-testing resource.

The third milestone is quantitative baseline evaluation. Once the scenarios have ground-truth labels, the existing decision logic can be measured using conflict-detection and alert quality metrics. This stage establishes a baseline against which future improvements can be compared. It also provides evidence about where the simplified model performs well and where it requires refinement.

The fourth milestone is model enrichment. Aircraft movement can be made more realistic, environmental state can become dynamic, and uncertainty can be introduced. Each enhancement should be evaluated separately so that the research team can identify which change produced an improvement. This staged approach is preferable to changing multiple components simultaneously.

The fifth milestone is advanced AI experimentation. A machine-learning or optimization component can be introduced after the baseline has been measured. The new component should operate on the same scenario and evaluation framework, allowing direct comparison. If the advanced model does not improve the relevant metrics or produces less interpretable behavior, the baseline may remain preferable for the prototype.

The final milestone is research dissemination. A mature version of the platform can provide the code, scenario definitions, evaluation data where permitted, experiment configuration, and documented results alongside the paper. This would allow reviewers and other students to reproduce the core experiments and extend the platform for additional research questions.
